ABSTRACT

We investigate the correlation between CO and H\textsc{i} emission in 18 nearby galaxies from the CARMA Survey Toward IR-Bright Nearby Galaxies (STING) at sub-kpc and kpc scales. Our sample, spanning a wide range in stellar mass and metallicity, reveals evidence for a metallicity dependence of the H\textsc{i} column density measured in regions exhibiting CO emission. Such a dependence is predicted by the equilibrium model of McKee and Krumholz, which balances H\textsc{2} formation and dissociation. The observed H\textsc{i} column density is often smaller than predicted by the model, an effect we attribute to unresolved clumping, although values close to the model prediction are also seen. We do not observe H\textsc{i} column densities much larger than predicted, as might be expected were there a diffuse H\textsc{i} component that did not contribute to H\textsc{2} shielding. We also find that the H\textsc{2} column density inferred from CO correlates strongly with the stellar surface density, suggesting that the local supply of molecular gas is tightly regulated by the stellar disk.

Key words: galaxies: ISM – ISM: atoms – ISM: molecules

Online-only material: color figures

1. INTRODUCTION

Molecular gas in galaxies provides the raw material for star formation (e.g., McKee & Ostriker 2007), yet in most galaxies the interstellar medium (ISM) is predominantly atomic. Understanding how the conversion of atomic-to-molecular gas is related to galaxy global properties, e.g., mass, morphology, and metallicity, is therefore critical to predicting the dense gas fraction and hence the star formation rate (e.g., Lada et al. 2012). Resolved studies of the spatial distribution of molecular and atomic gas over a wide variety of nearby galaxies can be used to test proposed theories of ISM phase balance (e.g., Krumholz et al. 2009; Ostriker et al. 2010) and constrain the evolution of the ISM through cosmic time (e.g., Obreschkow et al. 2009; Bauermeister et al. 2010).

Over the past few decades, the 21 cm H\textsc{i} line and the 3 mm CO J = 1–0 line have been the primary methods to study the atomic and molecular gas components of nearby galaxies. The major reasons for using CO as a molecular gas tracer are its intrinsic brightness, modest excitation requirements, high abundance relative to H\textsc{2}, and accessibility to ground-based radio telescopes. Thus, despite the uncertainty in converting CO intensity to H\textsc{2} column density, typically performed using a constant scaling factor (“X-factor”; see Bolatto et al. 2013 for a recent review), CO remains the preferred method to survey the molecular gas content in galaxies. In contrast to CO, the inference of atomic gas mass from 21 cm emission is fairly direct, except in cases where the optical depth is thought to be significant. The primary challenge for systematically mapping H\textsc{i} in nearby galaxies is achieving both high angular resolution and sensitivity.

While early observations (e.g., Tacconi & Young 1986) had already indicated that H\textsc{i} and CO are distributed very differently in galaxies, with CO largely confined to the stellar disk, the comparison of radial H\textsc{i} and CO profiles across significant samples by Wong & Blitz (2002), Blitz & Rosolowsky (2006, hereafter BR06), and Leroy et al. (2008) revealed strong radial trends in the ratio of molecular to atomic hydrogen mass surface density, $R_{\text{mol}} \equiv \Sigma_{\text{H}_2}/\Sigma_{\text{H}\textsc{i}}$, which exhibit a tight correlation with a simple estimate of the midplane gas pressure based on hydrostatic equilibrium, $P_{\text{mp}} \propto \Sigma_{\text{gas}} \sqrt{\rho_c}$. This supported an earlier model by Elmegreen (1993) that interstellar pressure (and, secondarily, radiation field) govern the H\textsc{i} to H\textsc{2} transition. Note that $R_{\text{mol}}$ is related to the quantity $f_{\text{mol}} \equiv \Sigma_{\text{H}_2}/\Sigma_{\text{gas}} = R_{\text{mol}}/(1 + R_{\text{mol}})$, which is more properly referred to as the molecular gas fraction but exhibits much less dynamic range.

In recent years there has been a resurgence of interest in theoretical modeling of the H\textsc{i} to H\textsc{2} transition, including attempts to model the physical and chemical processes on small scales in a time-dependent manner (Pelupessy et al. 2006; Glover et al. 2010), as well as construct analytic equilibrium models suitable for cloud scales and larger. The latter approach has been outlined in a series of papers by Krumholz et al. (2008), Krumholz et al. (2009, hereafter KMT09), and McKee & Krumholz (2010, hereafter MKT10). Roughly speaking, an
equilibrium $H_2$ abundance arises from a competition between $H_2$ formation on grains and photodissociation by UV radiation. Thus, for a given cloud the molecular gas fraction depends on the dust optical depth of the cloud (since dust excludes dissociating radiation and encourages molecule formation) and the strength of the external radiation field. A dependence of $f_{\text{mol}}$ on metallicity enters via the correlation of metallicity with the dust abundance. Already there have been attempts to apply the empirical $R_{\text{mol}}=P_{\text{dust}}$ relation of BR06 and the theoretical predictions for $f_{\text{mol}}$ of KMT09 and MK10 to cosmological contexts (e.g., Obreschkow et al. 2009; Fu et al. 2010; Lagos et al. 2011; Kuhlen et al. 2012), underscoring the importance of testing their applicability across a broader range of galaxies.

The CARMA Survey Toward IR-Bright Nearby Galaxies (STING) is a major effort to measure the molecular gas properties and their relation to star formation in a sample of ~20 nearby star-forming galaxies. Unlike the precursor BIMA Survey of Nearby Galaxies (SONG; Helfer et al. 2003), the STING sample is specifically chosen to cover a wide range in stellar mass, and thus covers a wide range in associated galaxy properties (star formation rate, color, luminosity, metallicity, etc.). Supplementing STING CO data with ancillary multi-wavelength data from the ultraviolet (UV) to infrared (IR), Rahman et al. (2011) studied the spatially resolved star formation law and its sensitivity to different analysis methods in NGC 4254, and have recently extended this study to the full STING sample (Rahman et al. 2012). The molecular gas data from the STING survey also permit a study of atomic-to-molecular gas transition, which is the subject of this Letter. We compare the STING CO J = 1-0 dataset with archival H I data from the NRAO Very Large Array (VLA) to examine the atomic and molecular gas relation in 18 galaxies of the STING sample on sub-kpc to kpc scales. Our principal observational result is a clear dependence of $H_1$ column density on metallicity, and an equally striking dependence of $H_2$ column density on stellar surface density. A more detailed presentation of these data and comparison with theoretical models will be presented in a future work (Xue et al., in preparation, hereafter X14).

2. OBSERVATIONS AND DATA REDUCTION

The STING sample is composed of northern ($\delta > -20^\circ$), moderately inclined ($i < 75^\circ$) galaxies within 45 Mpc selected from the IRAS Revised Bright Galaxy Survey (Sanders et al. 2003) to sample a wide range of stellar masses (and consequently, ISM metallicity). CO observations were conducted in the C and D configurations of CARMA to yield a robustly weighted synthesized beam of 3″-4″ across a field of view extending to roughly half the optical radius. Calibration was performed using the MIRIAD package, but imaging and deconvolution were performed using CASA (McMullin et al. 2007), taking advantage of the multi-scale CLEAN feature of CASA to better recover extended structures by searching for model components on multiple scales (in our case, point sources as well as Gaussians twice and five times the width of the synthesized beam). For four galaxies (NGC 3198, 4254, 4536, and 5713) with CO J = 2–1 single-dish maps from the HERACLES project (Leroy et al. 2009, 2013b), a detailed comparison in X14 suggests that the CARMA maps recover $\gtrsim 75\%$ of the flux within the field of view.

We searched the NRAO Data Archive for public H I 21 cm data of STING galaxies obtained in B, C, or D configurations of the VLA with adequate velocity resolution ($\lesssim 20$ km s$^{-1}$) to separate line from continuum. Archival data were found for 19 out of the 23 galaxies, so the present study is restricted to this sub-sample. In addition, NGC 3593 shows unusually low deprojected H I column densities, which we attribute to its high inclination and significant optical depth in the 21 cm line, so we do not include it in the present analysis. To ensure the most uniform possible data processing, we reprocessed the visibility data using CASA. We employed multi-scale CLEAN for well-resolved galaxies (with map resolution $< 1$ kpc), and flagged regions with strong continuum emission ($T_b > 50$ K) as potentially susceptible to optical depth effects. Further details on the pipeline as well as data sources can be found in X14. The FWHM beam parameters of the resulting H I maps (major and minor axis and position angle (P.A.)) are given in Table 1, and set the limiting resolution for our analysis.

A smoothing and masking process was used to generate integrated line intensity images from the CO and H I data cubes. The cube was first smoothed along the spatial and velocity axes to increase the signal-to-noise ratio. A mask was then generated from the smoothed cube by starting at emission peaks defined by at least two consecutive >4σ channels (where σ is the rms noise in the smoothed cube) and expanding outward to a 2σ edge. This mask was then applied to the original cube, blanking regions outside the mask, before summing the velocity channels. Finally, the integrated intensity images were deprojected to face-on using the orientation parameters given in Table 1 after being regridded to a common pixel scale and smoothed to a common resolution (the latter chosen to achieve a circular beam when deprojected). For reference, Table 1 also gives, as a measure of the physical resolution, the length scale $r_{\text{phy}}$ corresponding to the deprojected H I beam using the median redshift-independent distance (e.g., from the Tully–Fisher method) reported by NED.

Face-on mass surface densities were calculated by using the optically thin assumption for H I and a CO-to-$H_2$ conversion factor of $\alpha_{\text{CO}} = 4.4 M_\odot$ pc$^{-2}$ (K km s$^{-1}$)$^{-1}$ for CO (e.g., Leroy et al. 2008). Reported surface densities include a factor of 1.36 to account for helium. The typical $\sigma$ uncertainty in the deprojected surface density, based on a typical integration window of 20 km s$^{-1}$ for CO and 40 km s$^{-1}$ for H I, is given in Table 1 and is appropriate for maps smoothed to the H I resolution. The deprojected intensity maps were sampled onto a hexagonal grid with a spacing between grid centers equal to the (deprojected) FWHM resolution of the image, following the methodology of Leroy et al. (2013b).

3. RESULTS

Figure 1(a) displays a point-by-point comparison of $\Sigma_{H_1}$ and $\Sigma_{H_2}$ at the limiting resolution of the H I data. Only regions where both H I and CO are detected at the >3σ level are shown. Open triangle symbols indicate H I measurements which are potentially contaminated by absorption in front of bright continuum emission, and a diagonal line labeled $R_{\text{mol}} = 1$

divides H I and H2-dominated regimes. Points are color coded by metallicity, determined as follows. For six objects lacking spectroscopic gas-phase metallicities (NGC 3147, 3486, 4151, 4605, 5371, and 6951), we derive a fiducial metallicity for the galaxy by applying the luminosity–metallicity relation of Moustakas et al. (2010). For four galaxies (NGC 1637, 3198, 4254, and 4654) for which a metallicity gradient has been determined from multiple spectroscopic measurements, we determine a local metallicity appropriate to each grid sample. For the remaining galaxies, we assign a single metallicity value (given in Table 1) across the galaxy, based on published H I region spectroscopy. (Since the gradients, when measured, are typically around ~0.5 dex per R25, and our observations are confined to R ~ 0.5 R25, inclusion or omission of a gradient has little effect on our results.) We find that points for a given galaxy tend to be distributed vertically, consistent with a nearly constant metallicity dependence of ΣH2. Higher values of ΣH∗ may be subject to less beam dilution and may better reflect the conditions under which the MK10 model is directly applicable (i.e., a resolved GMC complex and its atomic envelope). This may account for the tendency for ΣH∗/ΣH∗,MK10 to approach unity for larger ΣH∗. Further discussion of this effect can be found in KM10.

To investigate trends in ΣH∗ independent of ΣH, Figures 1(c) and (d) plot values of ΣH against stellar mass surface density (Σ∗) and scaled galactocentric radius, with points still color coded by metallicity. The stellar mass surface density is inferred from Spitzer 3.6 μm imaging (S4G project; Sheth et al. 2010) using Σ∗ = 317.7 × f3.6 (Eskew et al. 2012), where f3.6 is the background-subtracted 3.6 μm intensity in units of MJy sr−1. A strong correlation between ΣH∗ and Σ∗ is apparent, whereas no relationship with R/R25 is discernible in the sample as a whole.

Figure 2 provides another view of the ΣH∗–Σ∗ correlation by showing the same data as Figure 1(a), but with points color coded by Σ∗. At the full H I resolution (left panel), it is clear that ΣH2 correlates well with Σ∗, except for a few low-metallicity, H I-dominated galaxies where ΣH2 is low despite high Σ∗. Such exceptions may reveal inaccuracies in our assumption a uniform X-factor and uniform mass-to-light ratio in the IR. Average values of ΣH1 and ΣH2 (filled triangles), calculated in uniformly spaced logarithmic bins of Σ∗, underscore the much greater sensitivity of ΣH2 to Σ∗. The same trend is seen at a fixed resolution of 2 kpc (right panel), for the nine galaxies observed at sufficiently high resolution, except that several of the low-metallicity systems drop out of the sample. We stress that the CO measurements are taken over areas much larger than an individual GMC, so the observed trend probably originates from

changes in the covering fraction of GMCs rather than the actual surface density of GMCs.

4. DISCUSSION AND SUMMARY

We have compared the CO and H\textsubscript{i} surface brightnesses in individual apertures across 18 galactic disks from the CARMA STING sample spanning a range of metallicity and stellar mass. For simplicity we have plotted only independent quantities, avoiding intrinsic correlations between axes and assumptions about which combination of observables is most physically relevant for star formation or ISM physics. We also exclude nondetections (upper limits) from our analysis, so we are sensitive only to trends in CO-detected regions, which may be quite distinct from trends related to the detectability of CO (e.g., Saintonge et al. 2011).

Our principal result is a clear dependence of the characteristic H\textsubscript{i} column density on metallicity, as predicted by the models of KMT\textsubscript{09} and MK\textsubscript{10}. A similar result had been obtained for a dwarf galaxy sample by Fumagalli et al. (2010), but...
Solid triangles denote average values of $\Sigma$ (Leroy et al. 2013a), and be inconsistent with the bulk of the H Magellanic Cloud (SMC; Bolatto et al. 2011) and other galaxies are spatially distributed, as found by recent studies of the Small beam dilution. This would imply a difference in how H regions suggests that H $i$ with less of a clear metallicity dependence. We find that a major success of the MK10 model is its ability to predict the upper envelope of the observed $\Sigma_{HI}$ values, although the full distribution of points appears skewed below the predicted values by unresolved clumping within the beam. In particular, we do not see evidence for a diffuse H $i$ component that does not contribute to H$_2$ shielding and would therefore cause the observed $\Sigma_{HI}$ to exceed the model prediction. On the other hand, the fact that the predicted value of $\Sigma_{HI}$ is sometimes reached in low $\Sigma_{HI}$ regions suggests that H $i$ and CO need not suffer equally from beam dilution. This would imply a difference in how H $i$ and CO are spatially distributed, as found by recent studies of the Small Magellanic Cloud (SMC; Bolatto et al. 2011) and other galaxies (Leroy et al. 2013a), and be inconsistent with the bulk of the H $i$ being confined to the GMC envelopes modeled by MK10.

The correlation we observe between $\Sigma_{HI}$ and $\Sigma_*$ (setting aside low-metallicity systems for which the CO-to-H$_2$ conversion factor or 3.6 $\mu$m mass-to-light ratio may change) is hardly unexpected: a correspondence between CO and stellar radial profiles has been noted in many previous studies (e.g., Regan et al. 2001; Leroy et al. 2008, 2009; Schruba et al. 2011; Bigiel & Blitz 2012). Still, a comparison of Figures 1(a) and 2(a) vividly illustrates that the H $i$ and H$_2$ column densities of galactic disks appear to be governed by distinct processes. It is possible that the two trends we observe, lower $\Sigma_{HI}$ with higher metallicity (which often associates with higher $\Sigma_*$) and higher $\Sigma_{HI}$ with higher $\Sigma_*$, reinforce each other to produce a tight correlation of $R_{mol}$ with $\Sigma_*$ and estimates of hydrostatic pressure. However, since $\Sigma_*$ is dominated by the old stellar population, the processes that maintain its tight correlation with $\Sigma_{HI}$ remain unclear.

Studies probing GMC size scales find that the mass surface densities of GMCs are confined to a fairly narrow range (Bolatto et al. 2008; Roman-Duval et al. 2010), implying that kiloparsec-scale variations in $\Sigma_{HI}$ are largely reflecting the CO areal covering factor. We therefore hypothesize that GMCs are more abundant in regions of galaxies with higher $\Sigma_*$. A simple explanation is that star formation in GMCs is responsible for building up the stellar disk, resulting in a stellar disk that naturally mimics the H$_2$ distribution. However, observational evidence for GMC lifetimes of only a few tens of Myr (Kawamura et al. 2009; Murray 2011) raises the question of why the GMCs should be regenerated at the same locations in the disk. In present-day, highly evolved galaxies with gas fractions $\sim$0.1, it seems more plausible to argue that the H$_2$ distribution is governed by the stellar distribution. For instance, in the thermal equilibrium model of Ostriker et al. (2010), higher stellar density leads to higher pressure in the diffuse gas (as required by hydrostatic equilibrium), increasing the cooling rate and leading to the formation of bound clouds. Alternatively, H$_2$ consumption could be regulated by $\Sigma_*$-dependent gravitational instabilities (an idea explored further by Zheng et al. 2013), or a significant fraction of the total H$_2$ supply may be recycled from the old stellar disk (an idea explored further by Leitner & Kravtsov 2011).
