ABSTRACT
We compute the bispectrum of the 2dF Galaxy Redshift Survey (2dFGRS) and use it to measure the bias parameter of the galaxies. This parameter quantifies the strength of clustering of the galaxies relative to the mass in the Universe. By analysing 80 million triangle configurations in the wavenumber range $0.1 < k < 0.5 h^{-1}$ Mpc (i.e. on scales roughly between 5 and 30 $h^{-1}$ Mpc) we find that the linear bias parameter is consistent with unity: $b_1 = 1.04 \pm 0.11$, and the quadratic (nonlinear) bias is consistent with zero: $b_2 = -0.054 \pm 0.08$. Thus, at least on large scales, optically-selected galaxies do indeed trace the underlying mass distribution. The bias parameter can be combined with the 2dFGRS measurement of the redshift distortion parameter $\beta \approx \Omega_m^{0.6}/b_1$, to yield $\Omega_m = 0.27 \pm 0.06$ for the matter density of the Universe, a result which is determined entirely from this survey, independently of other datasets. Our measurement of the matter density of the Universe should be interpreted as $\Omega_m$ at the effective redshift of the survey ($z = 0.17$).

Key words: galaxies: clustering – cosmology: large-scale structure of Universe, cosmological parameters

1 INTRODUCTION
Clustering of mass in the Universe is believed to be a result of amplification by gravitational instability of small perturbations generated in the early Universe. Comparison with theoretical predictions offers the chance to test models of the generation of the perturbations, as well as putting important constraints on cosmological
parameters, which control the growth rate of the perturbations. A fundamental limitation on such a comparison has been that theoretical models predict the clustering properties of the mass in the Universe, and yet we have few direct measures of mass observationally. More readily observable is the distribution of luminous objects such as galaxies, so to compare with theory one has to determine, or assume, the relationship between the clustering of mass and the clustering of galaxies. In general one will expect these to differ, because the efficiency of galaxy formation may depend in some nontrivial way on the underlying mass distribution. The idea that structures may be ‘biased’ tracers of the mass distribution goes back to Kaiser (1984), who explained the high clustering strength of Abell clusters as due to their forming in high-density regions of the Universe. In addition, observations indicating that different types of galaxy cluster differently (e.g. Dressler 1980; Postman & Geller 1984; White, Tully & Davis 1988; Hamilton 1988; Lahav, Nemiﬀof & Piran 1990; Lahav & Saslaw 1992) show that they cannot all be unbiased tracers of the mass. Bias became an attractive way to reconcile the low velocities of galaxies with the high-density Einstein-de Sitter model favoured in the 1980s (e.g. Davis et al. 1985), but after the Cosmic Background Explorer (COBE) determined the amplitude of primordial fluctuations on large scales (Smoot et al. 1992), the ‘standard’ biased Cold Dark Matter (CDM) model became less popular. With the advent of more detailed datasets in the cosmic microwave background (CMB) and large-scale structure, it is possible to investigate and constrain a wider range of galaxy formation models, and an unknown bias relation adds uncertainty to the process.

Since the eﬃciency of galaxy formation is not well understood theoretically, it makes sense to try to measure it empirically from observations. When the perturbations are small (or on large, linear scales), it is diﬃcult to do this: there is a degeneracy between the unknown amplitude of the matter power spectrum \( P(k) \) and the degree of bias, \( b \), deﬁned such that the galaxy power spectrum is \( P_g(k) ≡ b^2 P(k) \). In principle, \( b \) may be a function of scale, through the wavenumber \( k \). At later times (or on smaller scales), however, the degeneracy is lifted by nonlinear effects. One feature of nonlinear gravitational evolution is that the overdensity ﬁeld \( δ(x) = \langle \rho(x) − \overline{\rho} \rangle / \rho \) becomes progressively more skewed towards high density. In principle skewness could also arise from non-Gaussian initial conditions; in practice this can be neglected (Verde et al. 2000), since CMB ﬂuctuations are consistent with Gaussian initial conditions (Komatsu et al. 2001; Santos et al. 2001). One can thus hope to exploit the gravitational skewness, but skewness could equally well arise from biasing, e.g. from a galaxy formation theory that increases at dense points in the mass ﬁeld. It is nevertheless possible to distinguish these two eﬀects by considering the shapes of isodensity regions. If the ﬁeld is unbiased, then the shapes of isodensity contours become ﬂattened, as gravitational instability accelerates collapse along the short axis of structures, leading to sheet-like and ﬁlamentary structures (e.g. Zeldovich 1970). If the galaxy ﬁeld is highly biased with the same power spectrum, however, the underlying mass ﬁeld is of low amplitude, and thus expected to be close to the initial ﬁeld, which is assumed to be Gaussian. These ﬁelds do not have highly-ﬂattened isodensity contours, as bias does not ﬂatten the contours; for example Eulerian bias preserves the contour shape. Thus there is a diﬀerence which could be detected, for example, by studying the three-point correlation function. In this paper, we exploit this eﬀect in Fourier space rather than real space, by analysing the bispectrum: \( \langle δ_k_1 δ_k_2 δ_k_3 \rangle \), where \( δ_k \) is the Fourier transform of the galaxy overdensity ﬁeld. The theory for the bispectrum is set out in Fry (1994), Hivon et al. (1995), Matarrese, Verde & Heavens (1997), Verde et al. (1998), Scoccimarro et al. (1998), Scoccimarro, Couchman & Frieman (1999) and Scoccimarro (2000). The galaxy survey we use is the Anglo-Australian Telescope 2 degree ﬁeld Galaxy Redshift Survey (Colless et al. 2001), as compiled in February 2001. It was created with the 2dF multi-ﬁbre spectrograph on the Anglo-Australian Telescope (Lewis et al. 2001), and currently consists of over 200,000 galaxies with redshifts up to about \( z = 0.3 \), broadly in two regions centred near the south and north galactic poles. See [http://www.mso.anu.edu.au/2dFGRS/] for further details. It is the ﬁrst survey which is large enough to put tight constraints on the bias parameter, as previous surveys are too shallow or too sparse. In this paper, we use 127,000 galaxies from the February 2001 compilation of the catalogue, truncated at \( 0.03 < z < 0.25 \).

The outline of the paper is as follows: in Section 2 we review the theory of growth of the bispectrum through gravitational instability, and discuss brieﬂy the eﬀects of redshift-space distortions; in Section 3 we illustrate our method of measuring the bias parameter. This method uses a new estimator of the bias parameter, which allows us to analyse many millions of \( k \)-vector triplets, thus drastically improving the signal to noise. In Section 4 we test the performance of the method. Finally in Section 5 we present our results and in Section 6 we discuss the implications of these results. An Appendix presents and describes in detail our new estimator of the bias parameter.

## 2 THE BISPECTRUM IN REAL AND REDSHIFT SPACE

The statistic we use to measure the bias of the galaxies is the bispectrum \( B \), which is related to the three-point correlation function in Fourier space. For the mass, this is deﬁned by

\[
\langle δ_{k_1} δ_{k_2} δ_{k_3} \rangle \equiv (2π^3)^2 B(k_1, k_2, k_3) \delta^3 (k_1 + k_2 + k_3)
\]

(1)

where \( δ_k = \int d^3 x \, δ(x) \exp(−i k \cdot x) \) is the Fourier transform of the mass overdensity \( δ(x) \equiv ρ(x)/ρ \), and \( δ^3 \) is the Dirac delta function, which shows that the bispectrum can be non-zero only if the \( k \)-vectors close to form a triangle.

The power spectrum \( P \) is similarly deﬁned by

\[
\langle δ_k δ_k' \rangle \equiv (2π^3)^2 P(k) \delta^3 (k + k').
\]

(2)

Analogous relations hold for the power spectrum and bispectrum of the galaxy distribution. We assume that the mass overdensity is a Gaussian random ﬁeld initially, as closely predicted by inﬂationary early universe models. Thus, at asymptotically early times the bispectrum is zero by symmetry. As gravitational instability develops, the ﬁeld becomes asymmetric, because nonlinear eﬀects skew the density ﬁeld to high densities. In this way, a non-zero bispectrum develops. In the mildly nonlinear regime, we use second-order perturbation theory to compute the expected bispectrum. To second order (in the overdensity \( δ \)) the Fourier coefﬁcients develop a nonlinear component which is proportional to \( δ^3 \), so the leading order term in the bispectrum grows like \( δ^4 \). Since the 2dFGRS is not a survey of mass density, to interpret the bispectrum measured from the survey we must make some assumption about the distribution of mass relative to the distribution of galaxies. To date, this uncertainty in the relationship between the mass and the galaxy distribution has placed a limitation on the usefulness of galaxy catalogues as a probe of cosmology. We make the assumption that the galaxy overdensity ﬁeld \( δ_g \) is related to the underlying mass overdensity by

\[
δ_g(\mathbf{x}) = \int \frac{d^3 k}{(2π)^3} P(k) \delta^3 (\mathbf{k}) \exp(−i \mathbf{k} \cdot \mathbf{x})
\]

(3)

where \( P(k) \) is the linear power spectrum and \( \delta^3 \) is the Dirac delta function.
some deterministic function, which we expand in a Taylor series as
(cf. Fry & Gaztanaga 1993)
\[ \delta_g = \sum_{i=0}^{\infty} b_i \delta_i^n. \]  
\[ (3) \]
We must keep terms up to \( i = 2 \), since these enter in the bispectrum
to the same level as second-order perturbation theory growth
terms, and we ignore higher-order terms. In order for \( \delta_g \) to have
zero mean, there is a (calculable) \( b_0 \) term, but we ignore it as it contributes
only to \( k = 0 \); \( b_1 \) is the linear bias parameter, and \( b_2 \) is the
quadratic bias parameter. A non-zero \( b_2 \) would indicate nonlinear
biasing of galaxies with respect to mass. Both of these parameters
are estimated in this paper from the 2dFGRS.

In real space, the two effects of nonlinear growth and nonlinear
bias contribute terms to a non-zero bispectrum:
\[ B(k_1, k_2, k_3) = P_g(k_1)P_g(k_2) \left[ \frac{J(k_1, k_2)}{b_1} + \frac{b_2}{b_1^2} \right] + \text{cyc.} \]
\[ (4) \]
where there are two additional cyclic terms (2,3) and (3,1). Details
of the theory leading to \[ (4) \] may be found in e.g. Matarrese,
Verde & Heavens (1997). We assume here that the galaxy power spectrum is
\( P_g(k) = b_1^2 P(k) \) (see Heavens, Matarrese & Verde 1998 for discussion of this point); \( J \) is a function that depends on the
shape of the triangle in \( k \)-space, but only weakly on cosmology (e.g. Bouchet et al. 1992; Bouchet et al. 1995; Catelan et al.
1995). Note that we assume a deterministic bias; other authors (e.g. Scherrer & Weinberg 1998; Dekel & Lahav 1999; Taruya, Koyama & Soda 1999) have investigated stochastic biases, where there is a
random component to the relationship between \( \delta \) and \( \delta_g \). In the case of stochastic bias the bispectrum has still the form of equation \( (3) \) but the function \( J \) is modified into \( J' \) in such a way that when the correlation coefficient of the stochastic bias \( r \) goes to unity (i.e. bias becomes deterministic), \( J' \to J \). Theoretical considerations suggest that \( r \approx 1 \) on scales of interest (e.g. Tegmark & Peebles 1998; Blanton et al. 2000; Seljak 2000).

In redshift space, both the power spectrum and the bispectrum
are modified by redshift-space distortions, arising because the
distance estimator (the redshift) is perturbed by peculiar velocities.
These distortions are radial in nature, and can be analysed, at some
expense in complexity, in radial and angular basis functions (e.g.
Fisher, Scharf & Lahav 1994; Heavens & Taylor 1995; Ballinger,
Heavens & Taylor 1995; Hamilton 1998; Tedros et al. 1999). Here,
we adopt the distant-observer approximation (Kaiser 1987), and
assume that nonlinear effects can be modelled by an incoherent small-
scale velocity field, characterised by the pairwise velocity dispersion \( \sigma_p \). The large-scale in-fall leads to distortions which depend on the
redshift distortion parameter \( \beta = \Omega_m^{0.6}/b_1 \), where \( \Omega_m \)
is the matter density parameter. Assuming in addition an exponential
distribution for the pairwise velocity the combined effect gives the
power spectrum in redshift space (denoted by subscript \( s \))
\[ P_s(k) = \frac{P(k)(1 + \beta \mu^2)^2}{1 + k^2 \mu^2 \sigma_p^2/2}, \]
\[ (5) \]
(e.g. Ballinger, Peacock & Heavens 1996; Hatton & Cole 1998),
where \( \mu \) is the cosine of the wavevector to the line of sight, which is
a fixed direction in the distant observer approximation. Other modifi-
cations have been suggested, such as a Gaussian, or exponential
one-particle velocity dispersion, which yield different functional
forms for the redshift distortion. Note that \( \sigma_p \) is usually written,
here, as implicitly divided by the Hubble constant. The bispectrum
is modified similarly, and again various modifications have been
proposed. We use the form
\[ B_s(k_1, k_2, k_3) = (B_{12} + B_{23} + B_{31}) \times \]
\[ (6) \]
\[ \left[ \frac{1}{2} \left( \frac{\alpha_1^2 k_1^2 \mu_1^2 \sigma_p^2}{2} \right) \left( \frac{1}{2} \left( \frac{\alpha_1^2 k_2^2 \mu_2^2 \sigma_p^2}{2} \right) \left( \frac{1}{2} \left( \frac{\alpha_1^2 k_3^2 \mu_3^2 \sigma_p^2}{2} \right) \right) \right]^{-1/2} \]
where
\[ B_{12} \equiv (1 + \beta \mu_1^2)(1 + \beta \mu_2^2) \times \]
\[ (7) \]
\[ \left[ \frac{\text{Ker}(k_1, k_2)}{b_1} + \frac{b_2}{b_1^2} \right] P_{0s}(k_1) P_{0s}(k_2) \]
and the kernel function \( \text{Ker} \) is \( J \) modified for redshift space (see Verde et al. 1998 equation (13) for the formula); \( \alpha_V \) is an adjustable
parameter which is shape-dependent, and must be calibrated from
simulations. Scoccimarro, Couchman & Frieman (1999) propose
an alternative for the denominator of \( (6) \), namely
\[ \left( 1 + \alpha_S k_1^2 \mu_1^2 + k_2^2 \mu_2^2 + k_3^2 \mu_3^2 \sigma_p^2 \right)^2 \]
\[ (8) \]
where the one-particle dispersion \( \sigma_p = \sigma_\nu/\sqrt{3} \) if the small-scale velocities are incoherent, and again the parameter \( \alpha_S \) needs to be
calibrated for different triangle shapes and cosmologies. We find
that the formula \( (6) \) recovers the true bias parameter in an ensemble
of simulated biased 2dFGRS catalogues with smaller scatter than \[ (8) \]. We see from \( (6) \) and \( (7) \) how the bispectrum can allow us
to measure the bias parameters. The left-hand side is potentially
observable, and we can hope to constrain \( b_1 \) and \( b_2 \) by considering
triangles of different shape (and hence different \( \text{Ker} \)).

3 METHOD
The previous Section shows the theoretical model for the bispec-
trum, and its dependence on the two parameters \( b_1 \) and \( b_2 \); note that,
from apart these two parameters, the bispectrum depends
on observable quantities such as \( \beta \), \( \sigma_p \), and \( P_0 \). The real-space galaxy
power spectrum is obtained from the angle-averaged redshift-space
power (cf. Verde et al. 1998):
\[ P(k) = P_s(k) \left[ \frac{4}{\sigma_p^4 k^4} \left( \frac{2 \beta^2}{3 \sigma_p^2 k^2} + \frac{\sqrt{(2 \beta^2 - 3 \beta^2)^2 + 4 \beta^2}}{k^2 \sigma_p^2} \tan^{-1} \left( \frac{k \sigma_p}{\sqrt{2}} \right) \right) \right]^{-1} \]
\[ (9) \]
The real-space power spectrum obtained this way agrees well with
the APM power estimated by Baugh & Efstathiou (1994) and Efs-
tathiou & Moody (2001). The input catalogue is based on a revised
and extended version of the APM galaxy catalogue (Maddox et al.
1990a).

The bispectrum and power spectrum data come from trans-
forming the galaxy distribution as follows. The galaxies are
weighted with the optimum weight for measuring the power spec-
trum (Feldman, Kaiser & Peacock 1994), which also minimises
the variance of higher-order correlation functions (Scoccimarro
2000). The weight is \( w(r) = 1/[1 + P_0 \tilde{m}(r)] \), where \( \tilde{m}(r) \) is
the average number density of galaxies at position \( r \), and \( P_0 \) is
the power spectrum to be estimated. For speed reasons, \( P_0 \) was
fixed at \( 5000 \, h^{-3} \, \text{Mpc}^3 \) so that a Fast Fourier transform could be
employed. This is optimal for minimising the variance at $k \approx 0.1 \, h \, \text{Mpc}^{-1}$, whereas our signal comes from wavenumbers with a smaller power, but in fact altering $P_b$ hardly changes the results.

### 3.1 Estimating the bispectrum

In this Section we describe how we estimate the bispectrum from the data, taking into account the survey shape, selection function and shot noise.

We follow Feldman, Kaiser & Peacock (1994) and Matarrese, Verde & Heavens (1997), and transform the field

$$F(r) \equiv \lambda w(r) [n(r) - \alpha n_s(r)]$$

where $\lambda$ is a constant to be determined, $n_s(r)$ is the number density of a random catalogue with the same selection function as the real catalogue, but with $1/\alpha$ times as many particles. If we set $\lambda = I_{22}^{-1/2}$, where

$$I_{ij} \equiv \int d^3 r \, w^i(r) \overline{w^j(r)}$$

(Matarrese, Verde & Heavens 1997), then the power spectrum may be estimated from

$$\langle |F_k|^2 \rangle = P_g(k) + \frac{I_{21}}{I_{22}} (1 + \alpha)$$

and the bispectrum from

$$\langle F_{k_1} F_{k_2} F_{k_3} \rangle = \frac{I_{33}}{I_{22}^2} \left[ B_g(k_1, k_2, k_3) + \frac{I_{32}}{I_{33}} \right]$$

$\alpha = 0$. An underlying assumption is that the power spectrum is roughly constant over the width of the survey window function in $k$ space. Because of the rather flat geometry of the survey regions, and the holes due to star drills, this criterion is not satisfied in detail. In practice, we have used multiple mock catalogues (Cole et al. 1998) with the same selection criteria as the survey regions to check that this assumption does not feed through into a biased estimate of the bias parameters. Also, the power spectrum and bispectrum estimates are convolved with the window function. This can lead to changes in shape from convolution, and erroneous interpretation of correlated noise as real features in the power spectrum. These effects are, however, not important in the wavenumber range ($0.1 \leq k \leq 0.5 \, h \, \text{Mpc}^{-1}$) which we use for the bispectrum analysis (Percival et al. 2001).

To compute the $F_k$, we generated random catalogues with approximately 5 times as many particles as the real catalogue, and analysed the North and South Galactic Pole regions (NGP & SGP) separately. We ignored the random fields present in the 2dFGRS as these complicate the window function and add very little information for the current analysis. Fast Fourier transforms were performed on a $512 \times 512 \times 256$ grid which encompassed all the particles, leading to a grid spacing of about $1 \, h^{-1} \, \text{Mpc}$.

### 3.2 Choice of triangles

We use the real parts of $F_{k_1} F_{k_2} F_{k_3}$ as our data, for triangles in $k$ space (i.e. where $k_1 + k_2 + k_3 = 0$). Each triangle allows us to estimate a linear combination of the parameters natural to this analysis: $c_1 \equiv 1/b_1$ and $c_2 \equiv b_2/b_1^2$, through equations (6) and (7). Note that we must use triangles of different shape (and hence different $K(\mathbf{k}_1, \mathbf{k}_2)$) to lift the degeneracy between nonlinear gravity and nonlinear bias. As explained in the introduction, this is equivalent to analysing the shapes of structures, which are different in the two cases.

There is clearly a huge number of possible triangles to investigate (many millions), and we are faced with a problem of how to choose the triangles to analyse. The problem is that triangles which have a wavevector in common will be correlated, through cross-terms in the 6-point function. A likelihood analysis as originally suggested in Matarrese, Verde & Heavens (1997) and Verde et al. (1998) with millions of correlated data is unfeasible, so we take a different approach. We use two sets of triangles of different configurations: one set with one wavevector twice the length of another, and another set with two wavevectors of common length. For the former, calibrations with mock catalogues give $\alpha_V = 1.8$, and the latter $\alpha_V = 1.0$. We set a lower limit to the wavenumber range of $k = 0.1 \, h \, \text{Mpc}^{-1}$, to avoid the effects of convolution with the window function (Percival et al. 2001). We set an upper limit of $k = 0.5 \, h \, \text{Mpc}^{-1}$ where, for the 2dFGRS power spectrum, shot noise begins to dominate the signal so that little further is

---

**Figure 1.** Measured (redshift-space) 2dFGRS dimensionless bispectrum from the SGP and NGP for the two chosen configurations. The dotted line shows the perturbation theory prediction for $b_2 = 1$, $b_3 = 0$ while the dashed and dot-dashed lines show the shot noise contributions. The error bars are obtained via Monte Carlo simulation of 16 mock 2dFGRS catalogues (see text for details).
We find that 16 mock catalogs are sufficient to estimate the error bars. The choice of the cosmological model is not important for the error estimate, however this choice of the cosmological model turns out to be not too far away from the model recovered "a posteriori".

4 MOCK CATALOGUES AND TESTS

We have used 16 mock catalogues from a Hubble Volume N-body simulation with $\Omega_m = 0.3$, $\Omega_L = 0.7$ (\'$\Lambda$CDM\' model), with the same selection function as the 2dF galaxy redshift survey (Cole et al. 1998). This includes both the radial selection function and an angular mask that reflects the varying completeness of the survey in February 2001. The catalogues contain mock galaxies whose positions are determined according to the prescription described in Cole et al. (1998). This is a 2-parameter exponential model based on the final density field, i.e. it does not conform to our assumption of equation (3). We will show that nevertheless the bispectrum method recovers the bias parameter $b_1$, defined by the square root of the ratio of the galaxy and matter power spectra. This is the crucial test, since it is this ratio that we wish to determine, as we can then translate the galaxy power spectrum to the underlying mass spectrum. For the simulated galaxies in the Hubble volume as a whole the square root of the power spectrum ratio varies between about 0.9 at large scales and 0.75 at $k = 0.5 \, h \, \text{Mpc}^{-1}$. Over the scales probed by our bispectrum triangles, the bias is roughly 0.8, but with an uncertainty which ultimately limits our error determination. The power spectrum of the simulated 2dFGRS catalogues varies a little, so we estimate $b_1 \equiv (P_g/P)^{1/2}$ individually for each catalogue (and individually for SGP and NGP), from the wavenumber range $0.1 - 0.5 \, h \, \text{Mpc}^{-1}$. This sets $\beta$ for each sample, and we fit the pairwise velocity dispersion $\sigma_v$ individually by requiring a good fit to the redshift-space power spectrum, using the real-to-redshift mapping of equation (9).

We then analyse the set of triangles for each simulation, as detailed above, and in Fig. 3 we show the error in the bias from 16 simulations in the SGP and NGP. The average bias in the estimator is consistent with zero for the SGP: $-0.01 \pm 0.03$, but shows a small bias of $0.10 \pm 0.04$ for the NGP. The sample rms of 0.11 for the SGP and 0.16 for the NGP are used in the analysis of the 2dFGRS.

We have used 16 mock catalogues from a Hubble Volume N-body simulation (see Sect. 4). In Fig. 2 we show the measured (redshift-space) 2dFGRS bispectrum from the SGP and NGP for the two chosen triangle configurations. The dotted line shows the perturbation theory prediction for $b_1 = 1$, $b_2 = 0$ while the dashed line shows the shot noise contribution. For the bispectrum, the shot noise contribution becomes dominant around $k = 0.5 \, h \, \text{Mpc}^{-1}$.

Figure 2. Error on the linear bias parameter from $\Lambda$CDM mock galaxy catalogues in the SGP (left) and NGP (right). The average bias in the estimator is consistent with zero for the SGP: $-0.01 \pm 0.03$, but shows a small bias of $0.10 \pm 0.04$ for the NGP. The sample rms of 0.11 for the SGP and 0.16 for the NGP are used in the analysis of the 2dFGRS.
In Fig. 3 we show $b_1$ recovered with the bispectrum method versus the underlying (true) $1/b_1 \equiv \sqrt{P/P_0}$ for 16 mock SGP and $\Lambda$CDM models. $1/b_1$ is the natural quantity in the analysis of the bispectrum (see equation 6). Note that the 2dFGRS has data in the NGP and SGP, reducing the error bar compared to these mock catalogues.

5 RESULTS

We analyse the catalogue as compiled in February 2001 (i.e. the same catalogue as in Percival et al. 2001), and we analyse the NGP and SGP regions separately; we excise the random fields entirely. This leaves us with 75792 and 51862 galaxies in the SGP and NGP respectively. The two survey regions give us a useful consistency check.

We initially present results fixing $\beta = 0.43$ and $\sigma_p = 385/H_0$ km s$^{-1}$ (3.85 $h^{-1}$ Mpc). These are the best-fitting values from the analysis of the 2dFGRS redshift-space correlation function (Peacock et al. 2001; Norberg et al. 2001a; see also Tegmark, Hamilton & Xu 2001). Note that this value of $\beta$ involves a bias parameter that is defined somewhat differently from ours, in terms of the correlation function. This bias parameter will coincide with our $b_1$ only if certain assumptions hold, such as if the overdensity in galaxies is everywhere $b_1$ times the mass overdensity. In due course, $\beta$ can be determined by analysis of the 2dFGRS power spectrum itself, but for the time being we assume that the two bias parameters are the same. Finally, we will marginalise over $\beta$ and $\sigma_p$.

5.1 Bias parameters

It is difficult to find a method to display in a single figure all of the information from the 80 million triangles used: for this reason we display only one configuration and for the SGP alone; adding other configurations (or the NGP) would complicate the figure. Fig. 4 shows the SGP data for configurations with two wavevectors of common length, along with the perturbation theory predictions for different combinations of the linear and quadratic bias parameters. The dashed and dot-dashed lines are the perturbation theory prediction for $b_1 = 1.3$, $b_2 = 0$ and $b_1 = 1.0$, $b_2 = 0.5$. The error bars come from the mock catalogues, and the offset between the centres of the error bars and the points shows the bias in the estimator.

Figure 3. $1/b_1$ recovered with the bispectrum method versus the underlying (true) $1/b_1 \equiv \sqrt{P/P_0}$ for 16 mock SGP simulations for the $\tau$CDM and $\Lambda$CDM models. $1/b_1$ is the natural quantity in the analysis of the bispectrum (see equation 6). Note that the 2dFGRS has data in the NGP and SGP, reducing the error bar compared to these mock catalogues.

Fixing the values of $\beta$ and $\sigma_p$, and including all of the triangles in the SGP gives as a raw result $b_1 = 1.06$, $b_2 = 0.01$. The NGP linear bias is slightly higher: $b_1 = 1.12$, $b_2 = -0.07$. Adjusting these results with the estimator bias obtained from the mock catalogues (Section 4), and associating an error from the mock catalogues gives

\begin{align}
    b_1 &= 1.07 \pm 0.11 \quad \text{SGP} \\
    b_1 &= 1.02 \pm 0.16 \quad \text{NGP}
\end{align}

and a combined minimum-variance weighted result of

\begin{align}
    b_1 &= 1.05 \pm 0.09.
\end{align}

Note that the estimator bias does not significantly alter the results: ignoring it increases the estimate by 0.03, much less than the statistical error.

Our estimate of the quadratic bias parameter from the NGP and SGP 2dFGRS is

\begin{align}
    b_2 &= -0.02 \pm 0.07, \quad \text{Natual}
\end{align}

with SGP and NGP individually giving $b_2 = 0.01 \pm 0.09$ and $-0.07 \pm 0.11$ respectively.

Thus we see that the 2dFGRS galaxies are perfectly consistent with tracing the underlying mass distribution on these scales (wavelengths $\lambda = 2\pi/k = 13$ to 63 $h^{-1}$ Mpc) i.e. $b_1$ is consistent with unity, and $b_2$ with zero.

The results depend mildly on the values of $\beta$ and $\sigma_p$ used. Marginalising over the distribution of these quantities estimated from the redshift-space correlation function (Peacock et al. 2001), the final results are virtually unchanged: $b_1 = 1.04 \pm 0.06$, $b_2 = -0.054 \pm 0.04$; adding these errors in quadrature with those of Fig. 6 gives our final estimates:

\begin{align}
    b_1 &= 1.04 \pm 0.11 \\
    b_2 &= -0.054 \pm 0.08.
\end{align}

5.2 Luminosity-dependent and scale-dependent bias

The 2dFGRS exhibits luminosity-dependent clustering (Norberg et al. 2001a; Norberg et al. 2001b), so it is reasonable to ask in what sense the galaxies in the 2dFGRS are unbiased. We have consistently used all the galaxies in the 2dFGRS NGP and SGP regions, to determine $\beta$ and the bias parameters. With the weighting scheme employed to measure $\beta$ and $b_1$, the weighted mean luminosity is $1.9 L_*$. From studies of the correlation function, Norberg et al. (2001) found a luminosity dependence in the relative bias of 2dFGRS galaxies: $b/b_* = 0.85 + 0.15 L/L_*$. If we use this relation to adjust our recovered bias to apply to $L_*$ galaxies, we find they could be slightly anti-biased, but they are still consistent with $b_1 = 1$ ($b_1 = 0.92 \pm 0.11$ assuming $b_1 = b$). The 2dFGRS galaxies, as a population, trace the mass extremely well.

On scale-dependence of the bias, it is worth noting that theoretical arguments (e.g. Mann, Peacock & Heavens 1998; Peacock & Smith 2000; Seljak 2000; Benson et al. 2000; Blanton et al. 2000; Berlind & Weinberg 2001) suggest that bias is expected to be constant on large scales (larger than a few $h^{-1}$ Mpc) and a scale-dependent bias is plausible on intermediate scales, but the scale dependence is expected to be weak. We find no evidence of scale-dependent bias (see Fig. 4). Both scale-dependence and luminosity-dependence may be explored in detail when the catalogue is complete.
The small size of the error bar is worth remarking on. For each pair over the uncertainty in \( \beta \) estimate Analysis of the redshift-space correlation function allows one to there is no evidence of scale dependent bias. This illustrates the level of bias in the estimator. The figure also shows that Inclusion of the remainder excludes both models at high confidence. The er- means that only 12 million triangles were used from the total 80 millions. This illustrates the level of bias in the estimator. The figure also shows that there is no evidence of scale dependent bias.

5.3 The matter density of the Universe

Analysis of the redshift-space correlation function allows one to estimate \( \beta = \frac{\Omega_m^{0.6}}{b_1} \) (Peacock et al. 2001), and this can be combined with our determination of \( b_1 \) to estimate the matter density parameter \( \Omega_m \). A strength of the result is that it is obtained from the 2dFGRS alone, independently of all other datasets. Following the same procedure as in the previous subsection, we marginalise over the uncertainty in \( \beta \) and \( \sigma_\beta \), to get:

\[
\Omega_m = 0.27 \pm 0.06. \tag{18}
\]

The small size of the error bar is worth remarking on. For each pair of values of \( \beta \) and \( \sigma_\beta \), we obtain an estimate of \( b_1 \). The estimates of \( \beta \) and \( b_1 \) are slightly anti-correlated, which leads to a slightly smaller scatter in \( \Omega_m \) than one would expect from the errors on \( \beta \) and \( b_1 \).

This result is consistent with other recent determinations by other methods such as combining CMB with large-scale structure or supernova measurements (e.g. Percival et al. 2001; Jaffe et al. 2001; Efstathiou et al. 2001) and from early weak lensing measurements (Hoekstra, Yee & Gladders 2001).

5.4 Comparison with previous work

Previous work has concentrated on using cumulants, although there have been two analyses (Feldman et al. 2001; Scoccimarro et al. 2001) of the bispectrum of infrared-selected galaxies observed with the Infrared Astronomy Satellite (IRAS; Fisher et al. 1995; Saunders et al. 2000). The IRAS samples are much smaller than the current 2dFGRS, and are also rather shallow, so shot noise and the radial nature of the redshift distortion is more severe than for the 2dFGRS. Nevertheless, bias estimates have been made, and reported with remarkably small error bars. The most accurate quoted values are from Feldman et al. (2001) \( 1/b_1 = 1.2^{\pm 0.3} \) for the PSCz survey (Saunders et al. 2000). This value of the linear bias parameter is consistent with our determinations, since IRAS galaxies have a power spectrum which is lower than optically selected galaxies, by a factor \( \sim 1.3^2 \) on the relevant scales (Peacock & Dodds 1994; Seaborne et al. 1999).

Studies of the skewness, kurtosis and higher-order moments of the optical galaxy distribution (e.g. Gaztanaga 1994; Szapudi & Szalay 1997; Hui & Gaztañaga 1999; Hoyle, Szapudi & Baugh 2000) have also shown consistency with a linear bias of unity, but here we are able to derive both the linear bias and the quadratic bias simultaneously. In addition, our present results are more accurate and convert these general indications of a low degree of bias into a strong constraint on theoretical models.

6 SUMMARY AND CONCLUSIONS

We have demonstrated through analysis of the bispectrum of the 2dFGRS that the optically-selected galaxies of the sample trace the matter density extremely well on large scales (Fourier modes with \( 0.1 < k < 0.5 h^{-1} \) Mpc\(^{-1} \) that approximately correspond to \( 30 < r < 5 h^{-1} \) Mpc). Specifically, the linear bias parameter is very close to unity, and the quadratic (nonlinear) bias is very close to zero. Ironically, this is exactly the assumption which used to be made decades ago in large-scale structure analysis, but which was questioned when the concept of biased galaxy formation was introduced (e.g. Kaiser 1984; Peacock & Heavens 1985; Bardeen et al. 1986; Dekel & Rees 1994). Theoretical arguments suggest that an initial bias at formation approaches unity with time, provided that galaxies are neither created nor destroyed (Fry 1996), and that the Universe does not become curvature- or vacuum-dominated in the meantime (Catelan, Matarrese & Porciani 1998). In any case, these assumptions will clearly fail at some level. Note that the effective depth of the survey is \( z = 0.17 \) and our measurement should be interpreted as the bias and \( \Omega_m \) at this epoch (for additional discussion see Lahav et al. 2001). Because of a tendency for bias to approach unity with time, we do not by this measurement rule out a significant bias of galaxies at formation time, but the unbiased nature of the galaxies today puts a significant constraint on theoretical models of galaxy formation.

Currently, we find no evidence of scale-dependent bias (see Fig. 4). The size of the survey at the present time does not allow us to place strong constraints on scale dependence or luminosity dependence of the bias parameter, or on the nature of biasing (e.g. deterministic, stochastic, Eulerian, Lagrangian etc.), but these issues will be explored with the completion of the survey. At some level nonlinear bias must appear on small scales, from the morphology-density relation (Dressler 1980; Hashimoto & Oemler 1999), but this is probably on too small scales for the perturbative method of this paper to be valid.

Our measurement of the matter density of the Universe \( \Omega_m = 0.27 \pm 0.06 \) should be interpreted as \( \Omega_m \) at the effective redshift of the survey. The extrapolation at \( z = 0 \) is model-dependent, but the changes this correction introduces are below the quoted error-bars for reasonable choices of model. Our measurement is in agreement with other independent determinations such as cosmic microwave background together with Hubble constant constraints (e.g. Jaffe et al. 2001; Efstathiou et al. 2001; Freedman et al. 2001) which also give comparable error bars.

It is worth re-emphasising that the analysis presented here relies only on the 2dFGRS dataset. It is also important that we not only conclude that the linear bias is essentially unity, but also the
quadratic (nonlinear) bias term is constrained to be very close to zero. Taken together, these measures argue powerfully that the 2dFGRS galaxies do indeed trace the mass on large scales. In addition to our findings, joint analysis of the 2dFGRS and CMB data (Lahav et al. 2001) also supports our conclusion that the 2dFGRS galaxies are unbiased. Different methods of measuring linear bias require different assumptions, and it is remarkable that such different methods agree on the basic cosmological model.

ACKNOWLEDGMENTS

LV is supported in part by NASA grant NAG5-7154, and acknowledges the University of Edinburgh for hospitality. AFH thanks Rutgers and Princeton Universities for hospitality. We are grateful to Raul Jimenez and David Spergel for useful discussions. The 2dF Galaxy Redshift Survey was made possible through the dedicated efforts of the staff of the Anglo-Australian Observatory, both in creating the 2dF instrument and in supporting it on the telescope.

REFERENCES

The pseudolikelihood. The maximum of the pseudolikelihood is still the correlation between different triangles, forming what we term an estimator by simply multiplying these likelihoods together, ignoring internally; we estimate it by Monte Carlo methods i.e. from asymptotically unbiased. The error, however, cannot be determined.

\[ \hat{c}_2 = \frac{2A_2A_{11} - A_1A_{12}}{A_{11}^2 - 4A_{11}A_{22}} \]

where

\[ A_{11} = \sum_{\gamma} \frac{R_{\gamma}^2}{2\sigma_{\gamma}^4} \]
\[ A_{22} = \sum_{\gamma} \frac{S_{\gamma}^2}{2\sigma_{\gamma}^4} \]
\[ A_{1} = \sum_{\gamma} (T_{\gamma} - B_{\gamma})R_{\gamma}/\sigma_{\gamma}^2 \]
\[ A_{2} = \sum_{\gamma} (T_{\gamma} - B_{\gamma})S_{\gamma}/\sigma_{\gamma}^2 \]
\[ A_{12} = \sum_{\gamma} R_{\gamma}S_{\gamma}/\sigma_{\gamma}^2 \]

We can also, if desired, compute \( c_1 \) on the assumption that \( c_2 = 0 \):

\[ \hat{c}_1 = \frac{A_1}{2A_{11}} \quad (c_2 \equiv 0) \]

The expressions for \( R_{\gamma}, S_{\gamma}, T_{\gamma} \) can easily be obtained from the expression for the bispectrum of Verde et al. (1998); Sections 2.3 and 2.4. We report them here for completeness. To obtain their corresponding real space quantities just set \( \sigma_0 = 0 \) and \( \beta = 0 \).

\[ R_{\gamma} = \left\{ \left[ J(k_1, k_2) + \mu^2 \beta K(k_1, k_3) \right]2P_\theta(k_1)P_\theta(k_2) \left(1 + \beta \mu_1^2 \right) + \text{cyclic} \right\} D_3 \]
\[ T_{\gamma} = \left\{ \left[ \mu_1^2 \mu_2^2 + \frac{\beta}{2} (\mu_1^2 + \mu_2^2) + \beta \mu_1 \mu_2 \left( \frac{k_1}{k_2} + \frac{k_2}{k_1} \right) \right] \right. 
\[ + \left. \frac{\beta}{2} \mu_1 \mu_2 \left( \frac{k_1^3}{k_2} + \frac{k_2^3}{k_1} \right) \right\} P_\theta(k_1)P_\theta(k_2) \left(1 + \beta \mu_1^2 \right) + \text{cyclic} \right\} D_3 \]
\[ + \left[ P_\theta(k_1) \left(1 + \beta \mu_1^2 \right) \right\} \left(1 + \sigma_0^2 \right) \left(1 + \sigma_0^2 \right) + \text{cyclic} \right\} D_3 \]

where \( D_3 \) denotes the damping term due to the incoherent small scale velocity dispersion (see eq. 6):
